INSTRUCTIONS FOR USE

Cigna / ASH Medical Coverage Policies are intended to provide guidance in interpreting certain standard benefit plans administered by Cigna Companies. Please note, the terms of a customer’s particular benefit plan document may differ significantly from the standard benefit plans upon which these Cigna / ASH Medical Coverage Policies are based. In the event of a conflict, a customer’s benefit plan document always supersedes the information in the Cigna / ASH Medical Coverage Policy. In the absence of a controlling federal or state coverage mandate, benefits are ultimately determined by the terms of the applicable benefit plan document. Determinations in each specific instance may require consideration of:

1) the terms of the applicable benefit plan document in effect on the date of service
2) any applicable laws/regulations
3) any relevant collateral source materials including Cigna-ASH Medical Coverage Policies and
4) the specific facts of the particular situation

Cigna / ASH Medical Coverage Policies relate exclusively to the administration of health benefit plans.

Cigna / ASH Medical Coverage Policies are not recommendations for treatment and should never be used as treatment guidelines.

Some information in these Coverage Policies may not apply to all benefit plans administered by Cigna. Certain Cigna Companies and/or lines of business only provide utilization review services to clients and do not make benefit determinations. References to standard benefit plan language and benefit determinations do not apply to those clients.

Coverage for sensory integration therapy (SIT), auditory integration therapy (AIT) or facilitated communication (FC) therapy varies across plans. Refer to the customer’s benefit plan document for coverage details.

Note: This Medical Coverage Policy does not address sensory desensitization therapy.

GUIDELINES

Experimental, Investigational, Unproven

Sensory integration therapy (SIT), auditory integration therapy (AIT) or facilitated communication (FC) therapy are each considered experimental, investigational or unproven for any indication.

DESCRIPTION

Sensory Integration Therapy (SIT)

Sensory Integrative Techniques (SIT), also known as Sensory Integrative Therapy, are performed to enhance sensory processing and promote adaptive responses to environmental demands by changing underlying...
neurological processing through the use of activities that challenge a child to gradually engage in more challenging tasks and thus produce more complex and adaptive responses. Simply, SIT has been proposed as a method to improve the way the brain processes and organizes external stimuli, such as touch, movement, body awareness, sight and sound. The ultimate goal of SIT is to improve cognitive, behavioral, and social functioning of children (Hayes, 2017).

**Auditory Integration Therapy (AIT)**

Auditory integration therapy or training (AIT) refers to listening to music that has been computer modified to remove frequencies to which an individual demonstrates hypersensitivities and to reduce the predictability of auditory patterns. The individual listens via headphones to a program of specially filtered and modulated music with wide frequency range. A special device is used to modify the music for the treatment sessions. The treatment program consists of 20 half-hour sessions during a 10- to 12-day period, with two sessions daily. Auditory thresholds are determined via audiograms. The audiogram is then reviewed for evidence of hyperacusis (i.e., an abnormal sensitivity to sound). A clinical history of sound sensitivities and behavior is also reviewed. Audiograms are repeated midway and at the end of the training session to document progress and to determine whether further treatment sessions are necessary. AIT is usually provided by a speech-pathologist or audiologist.

**Facilitated Communication (FC)**

Facilitated Communication (FC) is a method of providing assistance to a nonverbal person by typing out words using a typewriter, computer keyboard, or other communication device. FC involves supporting the individual’s hand to make it easier for him or her to indicate the letters that are chosen sequentially to develop the communicative statement.

**GENERAL BACKGROUND**

**Sensory Integration Therapy**

SIT techniques are performed when a deficit in processing input from one of the sensory systems (e.g., vestibular, proprioceptive, tactile, visual or auditory) decreases an individual's ability to make adaptive sensory, motor and behavioral responses to environmental demands. Sensory stimulation is provided in combination with muscle activities, theoretically in order to improve how the brain processes and organizes sensory information. The therapeutic techniques may include deep brushing, swings for vestibular input, textures, bounce pads, scooter boards, weighted vests and other clothing, ramps and generally increasing or decreasing sensory diet depending on the needs of the child (Shaw, 2002). SIT has been proposed as a treatment of developmental disorders in patients with established dysfunction of sensory processing, e.g., children with autism, attention deficit hyperactivity disorder (ADHD), brain injuries, fetal alcohol syndrome, and neurotransmitter disease. Sensory integration therapy may be offered by occupational and physical therapists. Practitioners have used SIT for years selecting patients who demonstrate a variety of problems, including sensory defensiveness, over-reactivity to environmental stimuli, attention difficulties, and behavioral problems. Sensory integration techniques are used to organize the sensory system by involvement of full body movements that provide vestibular, proprioceptive and tactile stimulation. As mentioned, brushes, swings, balls, and other specially designed therapeutic or recreational equipment are used to provide these stimuli. Proponents believe the goal of SIT is to improve the way the brain processes and organizes sensations, as opposed to teaching higher order skills themselves. Therapy usually involves activities that provide vestibular, proprioceptive, and tactile stimuli, which are selected to match specific sensory processing deficits of the child. For example, swings may be used to incorporate vestibular input, while trapeze bars and large foam pillows or mats may be used to stimulate somatosensory pathways of proprioception and deep touch. Tactile reception may be addressed through a variety of activities and surface textures involving light touch. Sensory integration techniques are generally associated with pediatric populations. Advocates have proposed SIT as a treatment for developmental disorders in patients with established dysfunction of sensory processing, [e.g., children with autism, attention deficit hyperactivity disorder (ADHD), brain injuries, fetal alcohol syndrome, and neurotransmitter disease]. According to the American Academy of Pediatrics (AAP), (2012) "Sensory-based therapies are increasingly used by occupational therapists and sometimes by other types of therapists in treatment of children with developmental and behavioral disorders. Occupational therapy with the use of sensory-based therapies may be acceptable as one of the components of a comprehensive treatment plan. However, parents should be informed that the amount of research regarding the effectiveness of sensory integration therapy is limited and inconclusive." Additionally, it is unclear whether children who present with sensory-based problems have an actual "disorder" of the sensory pathways of the brain or whether these deficits are characteristics associated with other developmental and behavioral disorders. Because there is no
Universally accepted framework for diagnosis, sensory processing disorder generally should not be diagnosed. Other developmental and behavioral disorders must always be considered, and a thorough evaluation should be completed. Difficulty tolerating or processing sensory information is a characteristic that may be seen in many developmental behavioral disorders, including autism spectrum disorders, attention-deficit/hyperactivity disorder, developmental coordination disorders, and childhood anxiety disorders.

**Auditory Integration Therapy**

AIT has been proposed for improving abnormal sound sensitivity in individuals with behavioral disorders, including autism spectrum disorders. AIT aims to address the sensory problems which are said to cause discomfort and confusion in people with learning disabilities, including autism spectrum disorders. These hypersensitivities are believed to interfere with an individual’s attention, comprehension, and ability to learn. Thus, it has been proposed for improving abnormal sound sensitivity in these individuals with behavioral disorders, including autism spectrum disorders. Berard, whose method is the most widely studied, theorizes that auditory distortions may result in such behavioral disturbances as autism spectrum disorders, learning disabilities, depression, and aggressiveness. Berard suggests that AIT treats these distortions by exercising the middle ear muscles and auditory nervous system similar to physical therapy retraining muscles for orthopedic conditions. An audiogram, frequently the first step in the Berard method of AIT, is believed to help identify the presence of the auditory abnormalities and is used to monitor possible changes as a result of treatment. Berard claims that following AIT, children’s audiograms that previously had peaks and valleys, demonstrating areas of hyper- and hyposensitivity, are “flattened,” reflecting the elimination of auditory distortions and, subsequently, an improvement in behavioral abnormalities. According to Berard, optimal treatment consists of two half-hour sessions per day separated by a minimum of 3 hours, for 10 consecutive working days. A 2-day weekend interruption is acceptable. Despite current practice in the United States, Berard does not recommend follow-up sessions or any modifications to this treatment regimen. Results are evaluated by reviewing the audiogram obtained at the end of the 20 sessions and behavior changes at other post-treatment intervals.

**Facilitation Communication**

Facilitated communication bills itself as a way to allow individuals with autism, intellectual disability, or a condition like cerebral palsy to communicate by means of a “facilitator.” Facilitators provide pressure to the hand, wrist, or arm, guiding the individual to letters, words, or pictures—typically on a keyboard, smartphone, or tablet. Given it is a technique whereby individuals with disabilities and communication impairments allegedly select letters by typing on a keyboard while receiving physical support, emotional encouragement, and other communication supports from facilitators, the validity of FC stands or falls on the question of who is authoring the typed messages—the individual with a disability or the facilitator. Thus, FC has been at the center of debate because several scientific studies have suggested that facilitators may unintentionally influence the communication, perhaps to the extent of actually selecting the words themselves.

**LITERATURE REVIEW**

**Sensory Integration Therapy**

A meta-analysis was conducted for the purpose of determining whether existing studies of treatment using sensory integration approaches support the efficacy of this method (Vargas, et al., 1999). Sixteen studies were used to compare SIT with no treatment, and 16 studies were used to compare SIT with alternative treatments. The review noted that there was a significant difference between the average size of effect of the earlier studies compared to the more recent studies. The authors concluded that in the SIT and no treatment studies, the recent studies did not demonstrate an overall positive effect and that the sensory integration methods were found to be as effective as various alternative treatment methods. Dawson and Watling (2000) conducted a systematic review of the research regarding the effectiveness of interventions for sensory and motor abnormalities in autism. The interventions included SIT and auditory integration training (AIT). Four studies on the effectiveness of sensory integration therapy in autism that utilized objective measures of behavior to assess outcome were found. All but one had sample size of fewer than six subjects and none of the studies had a comparison group. One study that had a larger sample size and better design found no change in vocal behavior following brief participation in sensory activities. The review concluded that although sensory and motor impairments are commonly found in autism, the interventions developed to address them have not been well validated. In the case of SIT, it was noted, “there exist so few studies that conclusions cannot be drawn” (Dawson and Watling, 2000). In the case of AIT, it is noted that “there is no, or at best equivocal support for this intervention approach based on the available controlled studies” (Dawson and Watling, 2000). There is little known regarding which ages or subgroups of individuals are most likely to benefit from therapies addressing sensory and motor difficulties, and further research is recommended.
A review of SI outcomes research in relation to faithfulness of intervention to underlying therapeutic principles or fidelity was performed (Parham, et al., 2007). The review included 34 studies which were analyzed for consistency of intervention descriptions with the following elements: structural (e.g., equipment used, therapist training) and therapeutic process categories. The reviewers made the following findings:

- Most studies described structural elements related to therapeutic equipment and interveners’ profession.
- Only one of the 10 process elements, presentation of sensory opportunities, was addressed in all studies. Most studies described fewer than half of the process elements.
- Intervention descriptions in 35% of the studies were inconsistent with one process element, therapist-child collaboration. The authors note that the validity of SI outcomes studies is affected by weak fidelity in regard to the therapeutic process.

Several studies have been published that examined the effectiveness of SIT. While some of the studies indicated that there may be some effect noted with treatment with SIT, many of these studies involve small number of children and short follow-up time periods (Schaaf, et al., 2012; Wuang, et al., 2009; Fazlioglu, et al., 2008; Miller, et al., 2007; Watling and Dietz, 2007; Smith, et al., 2005). The peer-reviewed literature fails to demonstrate that SIT, compared with other treatments or with no treatment, provides clinically relevant, long-term improvements in outcomes in children with learning disabilities, Down syndrome, developmental disorders or SI disorders. Studies of SIT in children with cerebral palsy or autism are also lacking, and therefore the evidence is insufficient to evaluate SIT for these indications as well. May-Benson, et al. (2010) reported on a systematic review of literature on the effectiveness of sensory integration (SI) interventions on the ability of children with difficulty processing and integrating sensory information to engage in desired occupations and to apply these findings to occupational therapy practice. The review included 27 studies and the results indicated that the SI approach may result in positive outcomes in sensorimotor skills and motor planning; socialization, attention, and behavioral regulation; reading-related skills; participation in active play; and achievement of individualized goals. It appeared that gross motor skills, self-esteem, and reading gains may be sustained from three months to two years. Studies were limited by small sample sizes, variable intervention dosage, lack of fidelity to intervention, and selection of outcomes that may not be meaningful to clients and families or may not change with amount of treatment provided. The authors note that replication of findings with methodologically and theoretically sound studies is needed to support the current findings.

The AAP Council on Children with Disabilities published guidelines for the management of children with autism spectrum disorders. Regarding sensory integration therapy, the guidelines note “Sensory integration (SI) therapy often is used alone or as part of a broader program of occupational therapy for children with ASDs [autism spectrum disorders]. The goal of SI therapy is not to teach specific skills or behaviors but to remediate deficits in neurologic processing and integration of sensory information to allow the child to interact with the environment in a more adaptive fashion. Unusual sensory responses are common in children with ASDs, but there is not good evidence that these symptoms differentiate ASDs from other developmental disorders, and the efficacy of SI therapy has not been demonstrated objectively. Available studies are plagued by methodologic limitations, but proponents of SI note that higher-quality SI research is forthcoming.” (Myers, et al., 2007; Reaffirmed Dec 2010). The Agency for Healthcare Research and Quality (AHRQ) published a comparative effectiveness review of therapies for children with autism spectrum disorders. The review was prepared by the Vanderbilt Evidence-based Practice Center (Warren, et al., 2011). Among the allied health therapies in the review were sensory and auditory integration therapy. The research provided little support for their use. Specifically, all studies of sensory integration and music therapy were of poor quality. Pfeiffer et al. (2011) reported on a randomized study to address the effectiveness of sensory integration (SI) intervention in children with autism spectrum disorders. The children were randomized to SI intervention or fine motor intervention and received three sessions per week for six weeks. The study included 21 children diagnosed with autism and 16 with pervasive developmental disorder-not otherwise specified (PDD-NOS). Pretests and posttests measured social responsiveness, sensory processing, functional motor skills, and social–emotional factors. Results identified significant positive changes in Goal Attainment Scaling scores for both groups; more significant changes occurred in the SI group, and a significant decrease in autistic mannerisms occurred in the SI group. No other results were significant. The results are preliminary and further research is needed.

consistent protocols for sensory integration therapy are needed to evaluate effects for children with autism.

Controlled trials resulted in positive effects for sensory integration therapies, additional rigorous trials using they did not follow recommended protocols or target sensory processing problems. Although small randomized intervention studies. Studies of sensory-based interventions suggest that they may not be effective; however, and engagement in children with autism, for visual perception in children with Developmental Coordination Disorder (DCD), for sensory integration combined with perceptual–motor curriculum for visual, auditory, and tactile perception for children with suspected neurological problems, for occupational therapy using a sensory integration approach for decreasing externalizing and internalizing behaviors in children with problems in sensory processing, for engagement and reduced aggression in children with sensory modulation disorder, for improved social interaction and reduced disruptive behaviors in children with autism, for attention in children with autism, and to address tactile discrimination for children with suspected neurological problems. A level C recommendation is based on weak evidence that the intervention can improve outcomes, and the balance of the benefits and harms may result in a recommendation that occupational therapy practitioners routinely provide the intervention to eligible clients or in no recommendation because the balance of the benefits and harm is too close to justify a general recommendation. Specific performance skills evaluated were motor and praxis skills, sensory-perceptual skills, emotional regulation, and communication and social skills. There was insufficient evidence to provide a recommendation on sensory integration for academic and psychoeducational performance (e.g. math, reading, written performance).

The American Academy of Child and Adolescent Psychiatry (AACAP)’s practice parameter for “The assessment and treatment of children and adolescents with autism spectrum disorder” (Volkmar et al, 2014) stated that “There is a lack of evidence for most other forms of psychosocial intervention, although cognitive behavioral therapy has shown efficacy for anxiety and anger management in high functioning youth with ASD. Studies of sensory oriented interventions, such as auditory integration training, sensory integration therapy, and touch therapy/massage, have contained methodologic flaws and have yet to show replicable improvements”. A 2013 practice parameter for the assessment and treatment of children and adolescents with autism spectrum disorder states that “Studies of sensory oriented interventions, such as auditory integration training (AIT), sensory integration therapy (SIT) and touch therapy/massage, have contained methodological flaws and have yet to show replicable improvements.” Hayes (2014; reviewed 2015, 2016, 2017) conducted a technology assessment to evaluate the evidence on the safety and effectiveness of sensory integration therapy (SIT) for non-autistic children. According to Hayes, most of the reviewed studies found no benefit of SIT over time or were compared with control groups (no treatment or active interventions) across a range of outcomes for non-autistic children. None of the reviewed studies reported safety-related concerns or complications associated with SIT. Currently there is insufficient evidence regarding the effectiveness of SIT in non-autistic children to establish patient selection criteria given the varying diagnoses represented across studies reviewed (i.e., intellectual disabilities, cerebral palsy, motor coordination difficulties, Down Syndrome, sensory integration difficulties/sensory processing disorder) and absence of clear effects of SIT. The existing body of literature provides little evidence that SIT improves functioning for non-autistic children across time, or compared with no treatment or alternative interventions.

Case-Smith et al. (2015) completed a systematic review of sensory processing interventions for children with autism spectrum disorders. Children with autism spectrum disorders often exhibit sensory processing problems and receive interventions that target self-regulation. This systematic review examined the research evidence (2000-2012) of two forms of sensory interventions, sensory integration therapy and sensory-based intervention, for children with autism spectrum disorders and concurrent sensory processing problems. A total of 19 studies were reviewed: 5 examined the effects of sensory integration therapy and 14 sensory-based interventions. The studies defined sensory integration therapies as clinic-based interventions that use sensory-rich, child-directed activities to improve a child’s adaptive responses to sensory experiences. Sensory-based interventions are characterized as classroom-based interventions that use single-sensory strategies, for example, weighted vests or therapy balls, to influence a child’s state of arousal. Few positive effects were found in sensory-based intervention studies. Studies of sensory-based interventions suggest that they may not be effective; however, they did not follow recommended protocols or target sensory processing problems. Although small randomized controlled trials resulted in positive effects for sensory integration therapies, additional rigorous trials using consistent protocols for sensory integration therapy are needed to evaluate effects for children with autism.
spectrum disorders and sensory processing problems. Barton et al. (2015) conducted a comprehensive and methodologically sound evaluation of the efficacy of sensory-based treatments for children with disabilities. Thirty studies involving 856 participants met our inclusion criteria and were included in this review. Considerable heterogeneity was noted across studies in implementation, measurement, and study rigor. The research on sensory-based treatments is limited due to insubstantial treatment outcomes, weak experimental designs, or high risk of bias. Authors conclude that although many people use and advocate for the use of sensory-based treatments and there is a substantial empirical literature on sensory-based treatments for children with disabilities, insufficient evidence exists to support their use. Watling and Hauer (2015) completed a systematic review on the effectiveness of Ayres Sensory Integration® and Sensory-Based Interventions for People with Autism Spectrum Disorder. Of the 368 abstracts screened, only 23 met the inclusion criteria and were reviewed. Moderate evidence was found to support the use of ASI. The results for sensory-based methods were mixed. Schaaf et al. (2018) addressed the question "What is the efficacy of occupational therapy using Ayres Sensory Integration® (ASI) to support functioning and participation as defined by the International Classification of Functioning, Disability and Health for persons with challenges in processing and integrating sensory information that interfere with everyday life participation?" in a systematic review. Only 5 studies met inclusion criteria with only 3 being RCTs. Based on these studies, authors report the evidence is strong that ASI intervention demonstrates positive outcomes for improving individually generated goals. Moderate evidence supported improvements in impairment-level outcomes of improvement in autistic behaviors and skills-based outcomes of reduction in caregiver assistance with self-care activities. Child outcomes in play, sensory-motor, and language skills and reduced caregiver assistance with social skills had emerging but insufficient evidence. Kilroy et al. (2019) reviewed the neural underpinnings of sensory processing and integration in ASD by examining the literature on neurophysiological responses to sensory stimuli in individuals with ASD as well as structural and network organization using a variety of neuroimaging techniques. Authors noted that many aspects of Ayres' hypotheses about the nature of the disorder were found to be highly consistent with current literature on sensory processing in children with ASD but there are some discrepancies across various methodological techniques and ASD development. Further research is necessary to support ASI for individuals with ASD.

For adult patients, sensory integration techniques have been used for acquired sensory problems resulting from head trauma, illness, or acute neurologic events including cerebrovascular accidents. They are not appropriate for patients with progressive neurological conditions without potential for functional adaptation. Therapy is not considered a cure for sensory integrative impairments, but is used to facilitate the development of the patient's ability to process sensory input differently. Research studies are lacking for the adult population and SI therapy.

Due to the individual nature of sensory integration therapy and the large variation in individual therapists and patients, large multicenter randomized controlled trials are needed to evaluate the efficacy of this intervention. The most direct evidence related to outcomes from SI therapy comes from small randomized trials. Although some of the studies demonstrated some improvements on subsets of the outcomes measured, the studies are limited by small sizes, heterogeneous patient populations, and variable outcome measures. As a result, the evidence is insufficient to draw conclusions about the effects of and the most appropriate patient populations for SI therapy.

**Auditory Integration Training**

Although at least three AIT methods currently exist, the Berard method has emerged as the most commonly used in the United States and has been described most often in professional literature, which is limited. The Educational Audiology Association (EAA) issued a position statement regarding AIT (EAA, 1997). They stated that “Auditory integration therapy has not been proven to be a viable treatment for any disability. Only inconsistent, uncontrolled, anecdotal evidence has been provided to support claims of changes in auditory performance.” In addition, the position statement noted that without controls to protect against excessively loud auditory stimuli, AIT may cause harm to the auditory system. Mudford et al. (2000) performed a crossover study for the purpose of evaluating the benefits of auditory integration training for children with autism. There were 16 children who had been diagnosed with autism involved in the study, with all children receiving both treatments. There were at least four months between treatments. The control treatment was conducted by the auditory integration training providers in an identical room with identical procedures, with the difference being that the headphones used were nonfunctional. The measures included parent and teacher ratings of behavior, direct observational recordings, IQ, language, and social/adaptive tests. It was noted that significant differences tended to show that the control condition was superior on parent-rated measures of hyperactivity and on direct observational measures of ear-occlusion, and no difference was detected on teacher-rated measures. The children’s IQ and language comprehension did not increase; however, adaptive/social behavior scores and

Sensory and Auditory Integration Therapy - Facilitated Communication (CPG 149)
expressive language quotients decreased. The authors concluded that no children could be identified as benefiting from AIT clinically or educationally to any significant degree. American Speech-Language-Hearing Association (ASHA) prepared an evidenced-based technical report regarding AIT (ASHA, 2004). They noted that, despite approximately one decade of practice, this method has not met scientific standards for efficacy and safety that would justify its inclusion as a mainstream treatment for a variety of communication, behavioral, emotional and learning disorders. Sinha et al. (2004) completed a Cochrane Database Systematic Review to determine the effectiveness of AIT or other methods of sound therapy in individuals with autism spectrum disorders (ASD). Randomized controlled trials of adults or children with ASD were included using AIT or other sound therapies involving listening to music modified by filtering and modulation. Control groups could be no treatment, waiting list, usual therapy or placebo equivalent. Outcomes sought were changes in core and associated features of ASD, auditory processing, quality of life and adverse events. Meta-analysis was attempted but deemed inappropriate at present due to heterogeneity. No trials assessing sound therapies other than AIT were found. Six RCTs of AIT, including one cross-over trial, were identified with a total of 171 individuals aged 3-39 years. Four trials had fewer than 20 participants. Seventeen different outcome measures were used. Only two outcomes were used by three or more studies: Aberrant Behaviour Checklist (ABC) (5) and Fisher's Auditory Problems Checklist (FAPC) (3). Three studies (Bettison 1996, Zollweg 1997, Mudford 2000) did not demonstrate benefit of AIT over control conditions. The remaining trials (Veale 1993, Rimland 1995, Edelson 1999) reported improvements at 3 months for the AIT group based on improvements of total mean scores for the ABC, which is of questionable validity. Rimland (1995) also reported improvements at 3 months in the AIT group for ABC subgroup scores. No significant adverse effects of AIT were reported. Based on these results, authors concluded that more research is needed to inform parents', caregivers' and practitioners' decision making about this therapy for individuals with autism spectrum disorders.

The study addressing Tomatis therapy (Corbett 2008) described an improvement in language with no difference between treatment and control conditions and did not report on the behavioral outcomes that were used in the auditory integration therapy trials. Again, authors concluded that there is no evidence that auditory integration therapy or other sound therapies are effective as treatments for autism spectrum disorders. As synthesis of existing data has been limited by the disparate outcome measures used between studies, there is not studies including 182 participants that have been reported to date, only two (with an author in common), involving a total of 35 participants, report statistically significant improvements in the auditory integration therapy group and for only two outcome measures (Aberrant Behaviour Checklist and Fisher's Auditory Problems Checklist). The Agency for Healthcare Research and Quality (AHRQ, 2011) published a comparative effectiveness review of therapies for children with autism spectrum disorders. Among the allied health therapies in the review was auditory integration therapy. The research provided little support for its use. Specifically, two fair-quality studies of auditory integration showed no improvement associated with treatment. AHRQ also published a comparative effectiveness review on interventions for adolescents and young adults with ASD. Among the allied health therapies, studies of music therapy reported some improvements in social skills using invalid measures, thus there is little support for its use. The American Academy of Pediatrics (AAP) published a statement noting that as yet, there are no good controlled studies to support the use of AIT for children with autism. It is also noted that, until further information is available, the use of these treatments does not appear warranted at this time, except within research protocols (AAP, 1998/2006/2010). The American Academy of Audiology (2010) believes AIT by any name to be entirely investigational. The Academy believes that prospective, systematic research of this technique is needed to demonstrate its efficacy. Pursuant to Principle 5 of the Code of Ethics, the Academy believes that the experimental status of this technique must be clearly explained to consumers before they are entered into treatment. In 2011, Sinha published an update to the 2004 Cochrane review of AIT and other methods of sound therapy. At this time, authors identified six randomized controlled trials of auditory integration therapy and one of Tomatis therapy, involving a total of 182 individuals aged three to 39 years. Two were cross-over trials. Five trials had fewer than 20 participants. Twenty different outcome measures were used and only two outcomes were used by three or more studies. Again, meta-analysis was not possible due to very high heterogeneity or the presentation of data in unusable forms. The same conclusions were determined as the 2004 review for the AIT studies. As such, there is no evidence to support the use of auditory integration therapy at this time. The National Institute for Health and Clinical Excellence (NICE) published guidelines for the management and support of children and young people on the autism spectrum (NICE, 2013). The recommendations for treatment address interventions that should not be used for autism in children and young people including auditory integration training to manage speech and language. The American Academy of Child and Adolescent Psychiatry (AACAP)’s practice parameter (2014) for “The assessment and treatment of children and adolescents with autism spectrum disorder” stated that “There is a lack of evidence for most other forms of psychosocial intervention, although cognitive behavioral therapy has shown efficacy for anxiety and anger.
management in high functioning youth with ASD. Studies of sensory oriented interventions, such as auditory integration training, sensory integration therapy, and touch therapy/massage, have contained methodologic flaws and have yet to show replicable improvements. Given these findings, the published peer-reviewed scientific literature does not support the efficacy of AIT for the treatment of patients with learning disabilities, autism, and other behavioral disorders.

Auditory integration training (AIT) devices do not have FDA approval for treating medical, behavioral, or emotional disorders. The FDA has banned the importation of AIT devices such as AudioKinetron (SAPP, France) and Electronic Ear (Tomatis Electronics, France).

Facilitated Communication (FC)
In 1994, the American Psychological Association (APA) declared that there was no scientific evidence proving that FC worked—and that it constituted “immediate threats to the individual civil and human rights” of the person being facilitated. One of the primary concerns, both scientific and ethical, was the issue of “authorship”: whether the thoughts being expressed truly arise from the facilitated, and not the facilitator. The American Speech-Language-Hearing Association and the American Academy of Pediatrics joined in and by the late ’90s, 20 facilitated-communication proponents were largely dismissed as faith-healers or even predators. The May Institute’s National Autism Center, considered to be among the very best resources regarding evidence-based treatment of autism, found in both 2009 and again in 2015 in its National Standards Project that there is “little or no evidence in the scientific literature.” The AACAP published a policy statement regarding facilitated communication that states, “Studies have repeatedly demonstrated that FC is not a scientifically valid technique for individuals with autism or mental retardation. In particular, information obtained via FC should not be used to confirm or deny allegations of abuse or to make diagnostic or treatment decisions” (AACAP, 1993/2008). The AAP has published a statement regarding two treatments proposed for autism: AIT and facilitated communication. According to the AAP, there is good scientific data showing FC to be ineffective; therefore, its use is not an accepted treatment at this time. Currently available information does not support the claims of proponents that these treatments are efficacious. Its use does not appear warranted at this time, except within research protocols (AAP, 1998/2006/2010). AHRQ also published a comparative effectiveness review on interventions for adolescents and young adults with ASD. Among the allied health therapies, studies assessing facilitated communication noted little communication improvement associated with facilitation and some evidence of facilitator influence on participants’ responses (Warren et al., 2011).

Tostanoski et al. (2013) reviewed the history and damage caused by facilitated communication (FC) and highlights the parallels between FC and the Rapid Prompting Method (RPM). FC involves a therapist (or facilitator) supporting the hand of a person with autism while a message is typed on a letter board. Authors state that FC is widely acknowledged to be a pseudoscientific, unsafe, and unethical treatment for people with autism. RPM is a more recent intervention for people with autism that involves the facilitator holding and moving the letter board while the individual with autism moves their own hand. Those who espouse the perceived benefits of FC and RPM make strikingly similar claims of hidden intelligence and extraordinary communication abilities in people with autism following treatment. Authors conclude clients, proponents, and practitioners of RPM should demand scientific validation of RPM in order to ensure the safety of people with disabilities that are involved with RPM. Salovita et al. (2014) studied the authorship of messages produced through facilitated communication (FC) for all users of FC in two comprehensive schools in a small city in Finland. The participants were 11 children with intellectual disabilities, including autism, all having used FC from 1-3 years. The test conditions involved open and blind information-passing tasks in which the participants were directed to write down the contents of written or pictorial stimuli. The results failed to validate FC as a method of communication for any participant or facilitator. An analysis of the messages produced under the FC condition revealed a large degree of facilitator influence on the content of the messages produced. Additionally, FC impaired the performance of the two participants who had previously demonstrated some independent writing skills. Schlosser et al. (2014) reported a synthesis of the peer-reviewed literature on the question of authorship in FC. The International Society for Augmentative and Alternative Communication (ISAAC) formed an Ad Hoc Committee on FC and charged Schlosser et al. (2014) to synthesize the evidence base related to this question in order to develop a position statement. The authors considered synopses of systematic reviews, and systematic reviews, which were supplemented with individual studies not included in any prior reviews. Additionally, documents submitted by the membership were screened for inclusion. The evidence was classified into articles that provided (a) quantitative experimental data related to the authorship of messages, (b) quantitative descriptive data on the output generated through FC without testing of authorship, (c) qualitative descriptive data on the output generated via FC without testing of authorship, and (d) anecdotal reports in which writers shared their
perspectives on FC. Only documents with quantitative experimental data were analyzed for authorship. Results indicated unequivocal evidence for facilitator control: messages generated through FC are authored by the facilitators rather than the individuals with disabilities. Hence, FC is a technique that has no validity. Based on these results, there is insufficient evidence found in the medical literature regarding the effectiveness of this therapy. Associations have a long history stating their lack of support for FC. The International Society for Augmentative and Alternative Communication, in its own review of the science around FC, concluded in 2014 that all indications are that authorship stems from the facilitator, and not the facilitated. The Scottish Intercollegiate Guidelines Network (SIGN): The updated SIGN national clinical guideline on assessment, diagnosis and interventions for autism spectrum disorders states that facilitated communication should not be used as a means to communicate with adults, children and young people with ASD (2016). In 2016, NICE updated the clinical guideline, diagnosis and management of adults on the autism spectrum. The guideline recommendations for psychosocial interventions for the core symptoms of autism state to not provide facilitated communication for adults with autism. There is insufficient evidence found in the medical literature regarding the effectiveness of this therapy.

Coding/Billing Information

Note: 1) This list of codes may not be all-inclusive.
2) Deleted codes and codes which are not effective at the time the service is rendered may not be eligible for reimbursement.

Considered Experimental/Investigational/Unproven:
