INSTRUCTIONS FOR USE

The following Coverage Policy applies to health benefit plans administered by Cigna Companies. Certain Cigna Companies and/or lines of business only provide utilization review services to clients and do not make coverage determinations. References to standard benefit plan language and coverage determinations do not apply to those clients. Coverage Policies are intended to provide guidance in interpreting certain standard benefit plans administered by Cigna Companies. Please note, the terms of a customer's particular benefit plan document [Group Service Agreement, Evidence of Coverage, Certificate of Coverage, Summary Plan Description (SPD) or similar plan document] may differ significantly from the standard benefit plans upon which these Coverage Policies are based. For example, a customer's benefit plan document may contain a specific exclusion related to a topic addressed in a Coverage Policy. In the event of a conflict, a customer's benefit plan document always supersedes the information in the Coverage Policies. In the absence of a controlling federal or state coverage mandate, benefits are ultimately determined by the terms of the applicable benefit plan document. Coverage determinations in each specific instance require consideration of 1) the terms of the applicable benefit plan document in effect on the date of service; 2) any applicable laws/regulations; 3) any relevant collateral source materials including Coverage Policies and; 4) the specific facts of the particular situation. Coverage Policies relate exclusively to the administration of health benefit plans. Coverage Policies are not recommendations for treatment and should never be used as treatment guidelines. In certain markets, delegated vendor guidelines may be used to support medical necessity and other coverage determinations.

Overview

This Coverage Policy addresses high-intensity focused ultrasound (HIFU)/magnetic resonance (MR)-guided, focused ultrasound (MRgFUS) for various conditions, such as fibroids, and prostate, bone, and renal cancers.

Coverage Policy

High-intensity focused ultrasound (HIFU) is considered medically necessary as a local treatment for recurrent prostate cancer following radiation therapy when BOTH of the following criteria are met:

- positive, recent (i.e., repeat), transrectal ultrasound guided (TRUS) biopsy completed due to suspicion of local recurrence of prostate cancer
- candidate for local therapy alone as evidenced by **ALL** of the following:
 - original clinical stage T1-T2, NX or N0
 - recent PSA < 10 ng/mL
 - absence of distant metastases

Magnetic resonance (MR)-guided focused ultrasound (MRgFUS) is considered medically necessary for pain palliation in an individual with metastatic bone cancer who has failed or is not a candidate for radiotherapy.

High-intensity focused ultrasound (HIFU), including magnetic resonance (MR)-guided focused ultrasound (MRgFUS), is considered experimental, investigational or unproven for ANY other indication including as an initial treatment for localized prostate cancer.

General Background

High Intensity focused Ultrasound (HIFU)

High intensity focused ultrasound (HIFU) is a minimally-invasive surgical technique for the thermal ablation of both malignant and benign tumors and cessation of internal bleeding in injured vessels and organs with little damage to the surrounding tissue. HIFU has been proposed as an alternative to surgery for treatment of cancer and other tumor types, including but not limited to prostate, breast, brain, and renal cancer. It is also being used for palliation of pain (e.g., tumors metastasis to bone).

Prostate Cancer

HIFU has been proposed as treatment for localized prostate cancer and as salvage therapy for recurrent prostate cancer. Methods to manage localized prostate cancer include watchful waiting and active surveillance. Treatment options for localized prostate cancer include radical prostatectomy, radiotherapy, brachytherapy, cryotherapy, and intensity-modulated radiation therapy (IMRT). Treatment of recurrent cancer depends on factors such as the primary treatment method, extent of the cancer, and site of recurrence and includes options similar to those for localized prostate cancer. Transrectal HIFU involves the use of a probe to image the prostate and deliver timed bursts of heat to create coagulation necrosis in a targeted area. HIFU remains unique compared with other modalities for localized prostate cancer in that it has been proposed to result in much less adjacent tissue damage. This makes it a repeatable technology and thus potentially more salvageable by other techniques when it fails. A cooling balloon surrounding the probe protects the rectal mucosa from the high temperature. HIFU treatment can be repeated if necessary. This procedure is typically carried out in an outpatient setting and is performed under spinal or general anesthesia. Prolonged urinary retention secondary to edema and urethral sloughing have been the most common reported complications following primary HIFU treatment. Therefore, many of the current HIFU techniques include a pre-procedural TURP. Reported long-term complications following salvage HIFU include rectourethral fistulas, incontinence, rectal or perineal pain, erectile dysfunction and bladder neck contractures or urethral strictures (Ahmed and Emberton, 2016; Koch, 2011; Chaussy, et al., 2011; Rebillard, et al., 2008; Zelefsy, et al., 2008).

U.S. Food and Drug Administration (FDA): On June 7, 2018 the Focal One® (EDAP Technomed, Inc, Austin, TX) was determined to be substantially equivalent to the Ablatherm and Sonablate and is indicated for the ablation of prostate tissue (FDA, 2018). “The Focal One® is an evolution from the previous generation device, designed by EDAP: Ablatherm Integrated Imaging (K153023) and Ablatherm Fusion (K172285). The Focal One consists of the Focal One module with a software control system, an endorectal dynamic focusing probe, a leg holder, a set of single use disposables and a coupling liquid pouch”(FDA, 2018).

On July 28, 2017 the Ablatherm® Fusion was determined to be substantially equivalent to Ablatherm® Integrated Imaging and Sonablate® and is indicated for the ablation of prostate tissue. The purpose of the 510(k) submission was to add an optional feature that would provide MRI images and/or biopsies positions fused with the system’s live ultrasound imaging. This option is referred to as AblFusion (FDA, 2017). On November 6, 2015, the FDA granted 510(k) marketing clearance for the Ablatherm Integrated Imaging High-Intensity Focused Ultrasound (HIFU) device (EDAP Technomed, Inc., Austin, TX). The Ablatherm was determined to be substantially equivalent to the Sonablate device and is indicated for the ablation of prostate tissue. Ablatherm HIFU is administered via a transrectal probe under imaging guidance. The device uses HIFU to elevate the tissue temperature within the target zone of the prostate, resulting in tissue necrosis, while the surrounding tissue is kept at physiologically safe temperatures. Ablatherm HIFU treatment completely destroys the targeted prostate tissue (FDA, 2015).

On October 9, 2015, the Sonablate® 450 (SonaCare Medical, Inc., Charlotte, NC), and substantially equivalent devices of this generic type, was granted a change in FDA classification from class III to class II under the generic name high intensity ultrasound system for prostate tissue ablation. On December 21, 2016, the FDA granted 510(k) marketing clearance for the Sonablate® device (FDA, 2016).

Literature Review/Prostate: The peer-reviewed published literature consists of non-randomized controlled trials and case series (Jones, et al., 2018; Crouzet, et al., 2017; Ahmed, et al., 2012; Wu, et al., 2011; Asimakopoulos, et al., 2011; Boutier, et al., 2011; Chaussy, et al., 2011; Ganzer, et al., 2011; Koch, et al., 2011; Ripert, et al., 2011; Uchida, et al., 2011; Wu, et al., 2011; Crouzet, et al., 2010; Shoji, et al., 2010; Wilt, et al., 2008; Zacharakis, et al., 2008).

A 2017 Hayes Directory Report analyzed the available evidence (n=14 studies) on high-intensity focused ultrasound for salvage therapy of recurrent prostate cancer. The report included prospective and retrospective non-comparative trials (n=13 studies), and a single retrospective comparative trial. Individual study sample sizes ranged from 19–418 and studies evaluated outcomes that included PSA levels, negative biopsy rates, post-operative urinary and sexual function, quality of life (QOL), overall survival, prostate cancer mortality and treatment-related complications. HIFU treatment was only compared to cryoablation in one study. The mean follow-up range in studies was 14.8–53.5 months. Salvage HIFU was found to be relatively safe with acceptable efficacy outcomes in patients with localized prostate cancer that has recurred following primary treatment with EBRT or RP. Reported adverse effects included transient hematuria, urinary tract infection, bladder stones, epididymitis, and transient proctitis. The overall body of evidence was found to be of low quality due the absence of well-designed RCTs and individual study limitations. It was concluded that “the best available studies of ultrasound-guided HIFU for localized recurrent prostate cancer without metastatic disease at the time of treatment have consistently found that most patients had a reduction in PSA level, acceptable local tumor control, remained free of disease progression and survived for five years or longer after treatment.” However, additional, well-designed studies are needed to further compare HIFU for localized recurrent prostate cancer with alternative and established therapies before a determination can be made as to its long-term safety and effectiveness, particularly with regard to prostate cancer recurrence and mortality”. A 2019 review of this report did not identify any new evidence that would change these findings.

Another Hayes Directory Report (2016a) analyzed the available evidence (n=19 studies) on ultrasound-guided HIFU for the primary treatment of localized prostate cancer. The report included non-randomized comparative trials (n=12 studies), and prospective and retrospective non-comparative trials (n=7 studies). Individual study sample sizes ranged from 40–102 and studies evaluated outcomes that included PSA levels, negative biopsy rates, post-operative urinary and sexual function; quality of life (QOL), disease-free survival, prostate cancer mortality and treatment-related complications. HIFU treatment was compared to various therapies such as neoadjuvant androgen deprivation therapy, cryoablation and brachytherapy. The mean follow-up range in comparative studies was six–43 months and 47–120 months in non-comparative studies. None of the studies compared HIFU to radical prostatectomy or active surveillance. Whole-gland HIFU was found to have good safety and efficacy outcomes, and in comparative cohort studies, had similar or better efficacy than comparator treatment modalities such as cryoablation or brachytherapy. However, the overall body of evidence was of low quality due the absence of well-designed RCTs and individual study limitations. It was concluded that “the best available studies of ultrasound-guided HIFU for localized prostate cancer have consistently found that most patients remain free of disease progression and survive for five years or longer after treatment, and that the treatment is relatively safe. However, additional, well-designed studies are needed to further compare HIFU for localized prostate cancer with alternative and established therapies before a determination can be made as to its long-term safety and effectiveness, particularly with regard to survival and prostate cancer mortality”. A 2018 review of this report did not identify any new evidence that would change these findings.

Lukka et al. (2011) conducted a systematic review of the literature to evaluate the evidence comparing HIFU with standard treatment in patients with localized prostate cancer. No randomized controlled trials or meta-analyses were identified. Seven systematic reviews and two practice guidelines were identified; neither contained randomized controlled trials. Adjusting the selection criteria to include case series found 34 clinical studies of HIFU. Twenty-nine evaluated HIFU as the primary treatment and five examined HIFU as salvage treatment for recurrence after radiotherapy. In most studies the outcomes used to determine efficacy were negative biopsy rates or prostate-specific antigen (PSA) levels. The authors reported that the current evidence on HIFU use in

prostate cancer patients is of low quality, rendering it difficult to draw conclusions about its efficacy. Until results from case series are confirmed in prospective studies, the widespread use of HIFU is not supported.

Rebillard et al. (2008) conducted a systematic review of the literature. The authors reported that published clinical studies on HIFU are limited to case series; neither randomized studies comparing HIFU with another technique or active surveillance, nor studies with matched controls were found. Most papers originated in a few centers and it appears that several articles related to the same study with different numbers of patients and/or different times of follow-up. Most reports were of single-center studies. The authors reported that long-term follow-up studies are needed to further evaluate cancer-specific and overall survival rates. In addition, the efficacy and safety of HIFU as a primary therapy should be further evaluated in randomized controlled trials comparing it with other (minimally invasive) therapies. These are the same conclusions reported in a systematic review of the literature by Warmuth et al. (2010).

In an Agency for HealthCare Review and Quality (AHRQ) systematic review on comparative effectiveness and harms of treatments for clinically localized prostate cancer, HIFU is not discussed as a treatment option. The authors reported that assessment of the comparative effectiveness and harms of localized prostate cancer treatments is difficult because of limitations in the evidence (Wilt, et al., 2008).

Although not robust, evidence in the form of prospective and retrospective non-comparative studies suggests that HIFU is safe and effective for a subset of individuals for localized recurrent prostate cancer after treatment with radiation therapy. There is insufficient data to support HIFU as primary therapy for localized prostate cancer. Further well-designed, controlled trials are needed to establish long-term efficacy, safety and health outcomes of HIFU for prostate cancer treatment.

Professional Societies/Organizations

National Comprehensive Cancer Network® (NCCN®): The NCCN Clinical Practice Guidelines in Oncology Prostate Cancer stated that local therapies have been investigated for the treatment of primary and recurrent localized prostate cancer, with the goals of decreasing side effects and achieving the cancer control of other therapies. The NCCN panel recommends only cryosurgery, brachytherapy and HIFU for recurrent prostate surgery without metastasis after treatment with radiation therapy (NCCN, 2019a).

National Cancer Institute (NCI): In the 2019 Prostate Cancer Treatment Physician Data Query (PDQ®) HIFU is listed as a treatment option under clinical evaluation for patients with stage I or II prostate cancer.

American Cancer Society (ACS): HIFU is mentioned as a newer treatment for early stage prostate cancer. HIFU treatment has been used in some countries for a while, and is now available in the United States. Studies are under way to determine its safety and effectiveness. At this time, most doctors in the US don't consider HIFU to be a proven first-line treatment for prostate cancer (ACS, 2019).

American Urological Association (AUA), American Society for Radiation Oncology (ASTRO) and Society of Urologic Oncology (SUO): A joint guideline on clinically localized prostate cancer issued by AUA, ASTRO and SUO stated the following:

1. Clinicians should inform low- or intermediate-risk prostate cancer patients who are considering focal therapy or high intensity focused ultrasound (HIFU) that these interventions are not standard care options because comparative outcome evidence is lacking. (Expert Opinion)
2. Cryosurgery, focal therapy and HIFU treatments are not recommended for men with high-risk localized prostate cancer outside of a clinical trial. (Expert Opinion)
3. Clinicians should inform those localized prostate cancer patients considering focal therapy or HIFU that these treatment options lack robust evidence of efficacy. (Expert Opinion)

Additionally, it is stated that the guideline panel awaits the results of well-designed comparative clinical trials in order to define the appropriate role of HIFU in the management of localized prostate cancer (Sanda, et al., 2017).

American College of Radiology (ACR) Appropriateness Criteria®: The ACR's guideline on locally advanced, high-risk prostate cancer stated that HIFU is an option available for men with high-risk prostate cancer, however data is limited for this treatment modality (ACR 1996; Reviewed 2016).

Benign Prostatic Hypertrophy (BPH)

BPH is a noncancerous enlargement of the prostate gland. Symptoms of BPH include frequent urination, urgency, and excessive urination at night. Drug therapy may benefit patients with mild symptoms. Transurethral resection of the prostate has been established as the standard treatment for moderate to severe BPH. The procedure is done through a resectoscope and involves use of an electrocautery loop to remove a substantial portion of the prostate. HIFU is one of several less invasive alternatives to surgical resection of the prostate that are currently under clinical study. HIFU delivers targeted high-intensity ultrasound that rapidly elevates the temperature in a precise focal zone, thereby ablating excess prostate tissue.

Literature Review/BPH: Evidence in the published peer-reviewed medical literature evaluating HIFU for BPH consists primarily of few case series. Ohigashi et al. (2007) evaluated the efficacy and durability of three different minimally invasive therapies for BPH in a five-year prospective cohort study (n=103). Interventions were: transurethral microwave thermotherapy (n=34); transurethral needle ablation (n=29); and transrectal HIFU (n=40). There were no statistical differences found in efficacy or in the durability among the three interventions.

A case series (n=150) by Lü et al. (2007) was conducted on the safety and efficacy of transrectal HIFU for BPH. Outcomes included international prostate symptom score (IPSS), quality of life (QOL), uroflowmetric findings and transrectal ultrasound and incidence of complications. At the 12-month follow-up after the operation, maximum urine flow rate ($p<0.01$), post void residual ($p<0.01$) and prostatic volume ($p<0.05$) were significantly improved. However limitations of this study include its nonrandomized, uncontrolled design and short follow-up period.

Published guidelines by the Canadian Urological Association (2010) and The National Institute for Clinical Excellence (NICE) (United Kingdom) (NICE, 2015) do not recommend HIFU as an appropriate treatment for benign prostatic hyperplasia (BPH) because the role of high-intensity focused ultrasound for the treatment of BPH has not been established.

Glaucoma

Glaucoma is a chronic disorder involving increased pressure in the eye due to fluid build-up. There are several forms of glaucoma with open angle glaucoma (OAG) being the most common. The increased pressure associated with OAG can lead to optic neuropathies characterized by visual field loss and structural damage to the optic nerve fiber. If left untreated, glaucoma can result in partial or complete visual impairment. Currently, intraocular pressure (IOP) is the only treatable risk factor for glaucoma, and lowering IOP has proven beneficial in reducing the progression of loss of vision. In most cases, topical or oral medication is the first treatment of choice. For patients who are unwilling or unable to use medications or are unresponsive to medications, laser therapy or trabeculectomy, may be an option. Trabeculectomy is the current standard surgical technique for reduction of IOP, but it can result in extremely low IOP, causing ocular damage. Over time, the surgery may fail due to scar formation at the drainage site. HIFU has been proposed for treatment-refractory glaucoma.

The EyeOp1® HIFU system developed by EyeTechCare, S.A. (Rillieux la Pape, France) is intended to reduce the production of aqueous humor and subsequent IOP, without the potential thermal complications of cryoablation or laser therapy. The EyeOp1®, like other ablative procedures, targets the eye tissues responsible for production of aqueous humor. The system uses miniature transducers to perform thermocoagulation of ciliary processes without affecting surrounding ocular tissue (AHRQ, 2013). The EyeOp1 has not received U.S. FDA approval.

Literature Review/Glaucoma: There is currently a paucity of evidence in the published peer-reviewed medical literature evaluating the safety and effectiveness of HIFU for treatment-refractory glaucoma. The evidence evaluating HIFU for treatment-refractory glaucoma is primarily in the form of retrospective reviews, prospective case series, observational studies, and review articles (Dastiridou, et al., 2018; Deb-Joardar, et al., 2018; Graber, et al., 2018; Aptel, et al., 2016; Denis, et al., 2015). Clinical trials evaluating glaucoma treatment by cyclo-coagulation using HIFU are now underway.

Liver Cancer

Hepatocellular carcinoma (HCC) is relatively uncommon in the United States, but it is the most common primary malignancy of the liver. The only potentially curative treatments are surgical resection and liver transplantation. The majority of patients with primary or metastatic liver cancers are not suitable candidates for surgical resection at the time of diagnosis. In addition, chemotherapy and radiotherapy rarely produce a complete or sustained response in patients with advanced disease. HIFU is under investigation for the ablation of unresectable HCC.

Literature Review/Liver Cancer: HIFU for liver cancer has been evaluated primarily in case series with small patient populations. Luo et al. (2017) published a meta-analysis evaluating the evidence (n=30 studies) for the therapeutic effects of radiofrequency ablation compared to other ablative techniques including HIFU microwave ablation, percutaneous ethanol injection, and cryoablation on HCCs. The review consisted of cohort studies (n=14), and RCTs (n=16), with a single cohort study (n=103 patients) only referring to HIFU versus RFA. Outcomes measured were complete tumor ablation, overall survival, local tumor recurrence, and rate of complications. No obvious difference in therapeutic effects was found between HIFU and RFA. Overall survival rates were > 60% and complete tumor ablation were > 80% in both groups (p>0.05). Procedure-related complications were also comparable in both groups (p=0.06). The paucity of evidence on HIFU for HCC did not allow for meta-analysis. The authors noted that in general, additional well-designed RCTs are needed to support study results.

A Technology Brief published by Hayes reviewed the available literature on HIFU for treatment of hepatocellular carcinoma. The review included nonrandomized controlled trials (n=3 studies), case series (n=5 studies) and one retrospective cohort study. It was found that the available evidence suggests that HIFU was successful in producing complete or partial tumor necrosis in the majority of cases, although tumors ultimately recurred at various sites in up to 60% of patients. Survival time following HIFU was reported to vary across studies with one-year survival rates ranging from 43%–88%, and three-year survival rates ranging from 32%–62%. Tumor size and stage and disease severity, were found to influence results, since patients with smaller tumors or lower-stage disease had better survival rates. The reviewers concluded the overall quality of the evidence is low due to the lack of randomized controlled trials, and of studies that compare HIFU to treatments other than transarterial chemoembolization (TACE). The differences between studies in patient characteristics (e.g., tumor size, disease severity), measures of tumor response, and length of follow-up also impacted the quality of the available evidence. It was also noted that the published studies on this therapy have primarily been conducted in China. Therefore it is unclear whether the results can be applied to patients in other countries. Additional trials are needed to compare HIFU with other forms of treatment for unresectable HCC (Hayes 2012, reviewed 2014).

Li et al., (2007) compared HIFU plus supportive care (n=151) to supportive treatment alone (n=30). Tumor imaging parameters, serum AFP levels and symptom scores improved significantly in the HIFU group compared with the control group (all p<0.05). The one- and two-year survival rates were 50.0% and 30.9%, respectively, in the HIFU group, which were significantly greater than those (3.4% and 0%, respectively) in the control group (both p<0.01). No severe complications occurred during and after HIFU. Although study results suggest improved outcomes with HIFU, there are limitations which include lack of randomization and short-term follow-up.

Additional well-designed studies with larger patient populations are needed to support the safety and effectiveness of HIFU for the treatment of unresectable liver cancer.

Renal Cancer

Renal cell carcinoma (RCC), also referred to as kidney cancer, is a disease in which cancer cells are found in the lining of tubules in the kidney. Approximately 90% of renal tumors are RCCs. Symptoms of RCC may include: blood in the urine, loss of appetite, pain in the side that doesn't subside, weight loss, and anemia. Standard treatment available for patients with RCC includes surgery, chemotherapy, external or internal radiation therapy, and immunotherapy. Surgical excision in the form of a partial or radical nephrectomy is the accepted, often curative, treatment for stages I, II and III of RCC (NCCN, 2019). HIFU has been proposed as an intervention for small renal masses as well as advanced stage renal malignancy.

Literature Review/Renal Cancer: There is a paucity of studies in the published peer-reviewed scientific literature evaluating the safety and effectiveness of HIFU for renal cancer. Case series with small patient

populations (n=13–17) provide preliminary, but insufficient data from which to draw conclusions (Ritchie, et al., 2011; Ritchie, et al., 2010; Wu, et al., 2003). The role of HIFU has not been established for this indication.

Professional Societies/Organizations: The NCCN guideline on kidney cancer does not mention HIFU as a treatment option for renal cancer (NCCN, 2018).

Thyroid Nodules

Nodular thyroid tissue is common, however most thyroid nodules are benign. Causes of benign thyroid nodules include goiter and Hashimoto's thyroiditis. The incidence of malignancy, or thyroid cancer, depends on factors such as age, gender, radiation exposure, and family history. Treatment of thyroid cancer depends on the type of cancer, but may include radioiodine, thyroid hormone suppression and surgical removal of the thyroid gland. Minimally invasive treatments, such as percutaneous ethanol injection sclerotherapy, laser photocoagulation, and HIFU ablation, have been proposed as an alternative to surgery (Bandeira-Echtler, et al., 2014).

Literature Review/Thyroid Nodules: Few preliminary case series with small patient populations (n=10–13) evaluating HIFU for thyroid nodules have been reported in the medical peer-reviewed literature (Lang and Wu, 2017; Korkusuz, et al., 2014; Kovatcheva, et al., 2014). These preliminary study results suggest that HIFU may be a promising non-invasive tool for nodular thyroid disease, but the available evidence is insufficient to draw conclusions regarding HIFU for this indication.

Magnetic Resonance (MR)-Guided Focused Ultrasound (MRgFUS)

MRgFUS technology combines a high intensity focused ultrasound beam that heats and destroys targeted tissue non-invasively and magnetic resonance imaging (MRI) which visualizes anatomy, and continuously monitors the tissue effect. HIFU therapy using MR-guidance has been proposed for the treatment of uterine fibroids (leiomyomata), essential tremor, metastatic bone cancer, and other tumor types, however to date the most studied clinical application of MRgFUS has been treatment of leiomyomata.

Bone Cancer

Metastatic bone disease is one of the most common causes of cancer pain. Existing treatments include supportive measures, pharmacologic agents and radiation therapy. For treating pain associated with bone metastases, the aim of MRgFUS treatment is to destroy nerves in the bone surface surrounding the tumor and achieve local palliation of the metastatic lesion. The MRgFUS procedure is performed by a radiologist on an outpatient basis under conscious sedation and typically takes 1–2 hours depending on the number of areas to be treated. Patients are monitored for adverse events following the treatment, which commonly include sonication, position, or post-procedural pain (Hayes, 2016b, reviewed 2018).

U.S. Food and Drug Administration (FDA): In October 2012, the FDA granted a PMA for the ExAblate® System, Model 2000/2100/2100 (InSightec—North America, Dallas, TX). The device is indicated for pain palliation of metastatic bone cancer in patients 18 years of age or older who are suffering from bone pain due to metastatic disease and who are failures of standard radiation therapy, or not candidates for, or refused radiation therapy. The bone tumor to be treated must be visible on non-contrast MR and device accessible. The device was evaluated through an expedited review process. In addition to the unpublished randomized controlled trial upon which PMA approval was based, the manufacturer is required to conduct two post-approval studies to evaluate device performance under actual conditions of use and to further evaluate device safety (FDA, 2012).

Literature Review/Bone Cancer: A Hayes Technology Brief reviewed the available literature (n=3 studies) on MRgFUS for Palliation of Painful Bone Metastasis which included one fair quality RCT (n=147 patients) and two non-comparative studies of poor quality (n=18–37 patients). Selection criteria in studies were adult patients (≥ 18 years of age) whose metastatic bone pain was refractory to standard palliative treatments (e.g., radiation therapy) or those who refused or were not candidates for such treatment. Outcomes measured included pain control, pain medication intake, and QOL. Follow-up occurred through three months. In general, study results demonstrated significant improvements in pain and a decrease in pain medication use and no serious procedure-related adverse events were reported. However, the overall quality of the body of evidence on the efficacy and safety of MRgFUS for treatment of bone metastases was found to be low due to the small number of patients studied, the lack of controlled trials, and the absence of comparisons with standard treatments. Additional limitations of the studies were the loss to follow-up of some patients initially enrolled so that their

outcomes are unknown. Short-term follow-up periods made it difficult to determine durability of the pain relief delivered by MRgFUS, and whether the treatment deters disease progression. The authors concluded that while treatment appears to be safe, additional studies are needed to evaluate whether the treatment has any adverse effects on healthy surrounding tissue (Hayes, 2016b; reviewed 2018).

Lee et al (2017) published the results of a matched-pair study (n=63) to compare the therapeutic effects of MRgFUS (n=21) with those of conventional RT (n=42) as a first-line treatment for patients with painful bone metastasis. Patient selection criteria based on a retrospective electronic record review included the following:

- a solitary distinguishable painful bone metastasis
- no previous local therapy to the targeted bone lesion
- an unchanged schedule of systemic therapy, including chemotherapy, targeted therapy, hormonal therapy, and bone-targeted agents two weeks before and three months after the intervention with MRgFUS or RT
- survival and regular follow-up of \pm 3 months after the MRgFUS or RT intervention

Patients with a Mirels score > 7 , indicating impending pathological fracture, or with substantial comorbidities were excluded. The primary outcome was the clinical treatment response rate in terms of successful pain palliation at each evaluation point after either MRgFUS or RT. The secondary end points were a change in the pain score and morphine-equivalent daily dose, and treatment-related adverse events up to three months after treatment. The overall complete-response rates at three months were 43% and 29% in the MRgFUS and RT-treated patients ($p=0.2729$), respectively. The mean NRS pain score of the MRgFUS-treated patients was significantly lower at one week ($p<0.0001$), two weeks ($p=0.0188$), and three months ($p=0.0269$) after treatment than those of the RT-treated patients. Pain scores did not differ significantly at one- and two-month follow-up periods. The mean morphine-equivalent daily dose change from baseline at each evaluation point did not differ significantly between the two treatment groups. No adverse events above grade two were documented for either the MRgFUS or the RT patients. The median overall survival time was 12.7 and 9.8 months after treatment with MRgFUS and RT, respectively ($p=0.6184$). Acknowledged study limitations are the small sample size, retrospective design, and short follow-up time frame.

Hurwitz et al. in (2014) published results of a randomized, placebo-controlled, single-blind, multicenter trial (n=147) of MRgFUS in the palliation of pain from bone metastases. Patients were randomly assigned 3:1 to MRgFUS (n=112) or placebo treatment (n=35), which was identical to MRgFUS but with power off. The 3:1 imbalance in randomization was chosen to minimize ethical concerns with placebo treatment in this patient population. Patients included were at least 18 years old with a life expectancy \geq three months. Treatment was performed on bone metastases that were painful despite previous RT, otherwise unsuitable for RT or if RT was declined. Patients with \leq five painful lesions were eligible. Patients requiring surgical stabilization or with clinically significant comorbidities were excluded. The primary outcome was pain reduction after MRgFUS. Secondary outcomes included assessment of the treatment's impact on pain-related interference with patient functioning and treatment-related toxicity. Follow-up after the intervention was not completed by 26 patients in the MRgFUS arm and 23 patients in the placebo group. Response rate for the primary endpoint was 64.3% in the MRgFUS arm and 20.0% in the placebo group ($p<0.001$). MRgFUS was also found to perform better than placebo on the secondary endpoints assessing worst pain score ($p<0.001$) and the functional interference of pain on quality of life ($p<0.001$) at three months of follow-up. The most common treatment-related adverse event was pain related to the procedure, which occurred in 32.1% of MRgFUS patients. Overall 60.3% of all AEs resolved on the day of treatment. The authors acknowledged and explained study limitations which included double enrollment of five patients, difference in prior RT between study groups, imbalanced randomization, and the loss at follow-up. Study results indicate that MRgFUS may be a safe and effective noninvasive treatment option for pain from bone metastases in patients that have failed standard treatments. However additional randomized controlled trials are needed to confirm these findings.

Case series with small patient populations (n=7–80) and follow-up periods from one-five years have also evaluated the safety and effectiveness of imaging-guided HIFU for primary and metastatic bone tumors (Chen, et al., 2010; Li, et al., 2010). Survival rates of 89.8%, 72.3%, 60.5%, 50.5%, and 50.5%, at one, two, three, four, and five years, respectively have been reported (Chen, et al., 2010). Additional well-designed clinical trials with larger sample sizes are needed to further determine the role of HIFU for bone cancer. However, there is some

evidence in the published peer reviewed medical literature to suggest that MRgFUS is safe and effective for a subset of patients with metastatic bone cancer.

Professional Societies/Organizations: National Comprehensive Cancer Network® (NCCN®): According to NCCN guidelines for adult cancer pain, ablative strategies such as radiofrequency ablation (RF) or ultrasound ablation may also be performed to decrease both pain and the occurrence of skeletal related events (SREs). The NCCN notes that “several small studies have also demonstrated the palliative effects of HIFU treatment of bone lesions” (NCCN, 2019b).

Uterine Fibroids

Uterine leiomyomata, or fibroids, are benign tumors of the uterus that are made up of smooth muscle and the extracellular matrix proteins, collagen and elastin. Fibroids can lead to abnormal uterine bleeding, dysmenorrhea and noncyclic pelvic pain. They can also cause constipation, urinary frequency, and infertility, depending on their size and location. The current standards of care for the treatment of symptomatic fibroids include:

- nonsteroidal anti-inflammatory agents
- oral contraceptives
- pharmacological agents (gonadotropin-releasing hormone [GnRH]) for short-term therapy
- myomectomy (laparoscopic or open)
- uterine artery embolization
- hysterectomy

Myomectomy and uterine artery embolization are surgical options for patients who wish to preserve their fertility, since a hysterectomy would render these individuals permanently infertile.

MRgFUS has been proposed as a non-invasive technique used to ablate uterine fibroids in women who do not intend to become pregnant in the future. Although early studies showed that some fibroid symptoms decreased (n=71%) following the procedure, a high percentage of patients (n=21%) needed alternative surgical treatment for their fibroids within one year of having the procedure because their previous symptoms returned. Reported adverse effects of MRgFUS have included paresthesia, burns on the abdomen, excessive postoperative bleeding, and reactions to medication.

U.S. Food and Drug Administration (FDA): In November 2004, the FDA granted premarket approval (PMA) for an MRgFUS system for the proposed targeting and destruction of symptomatic fibroids. The ExAblate® 2000 System (InSightec—North America, Dallas, TX) is indicated for the ablation of symptomatic fibroids in women who have completed childbearing, do not intend to become pregnant, and have a uterine gestational size of less than 24 weeks. The ExAblate 2000 is contraindicated for use in women who have:

- MRI-related issues, such as metallic implants or sensitivity to MRI contrast agents
- obstructions in the treatment beam path, such as a scar, skin folds or irregularity, bowel, pubic bone, intrauterine device (IUD), surgical clips, or any hard implants
- fibroids that are close to sensitive organs, such as the bowel or bladder, or are outside the image area

Literature Review/Uterine Fibroids: Studies in the published peer-reviewed scientific literature evaluating the safety and effectiveness of MRgFUS ablation of uterine fibroids consists primarily of case series with few comparative trials.

Laughlin-Tommaso et al, (2019) conducted a randomized controlled trial (RCT) with a parallel observational cohort which compared the effectiveness of magnetic resonance imaging-guided focused ultrasound surgery (MRgFUS) and uterine artery embolization (UAE). Premenopausal women with symptomatic uterine fibroid tumors were included if they were age ≥ 25 years, had no evidence of high-grade squamous intraepithelial lesions, were able to give informed consent and attend all study visits. Patients (49) in the randomized control trial were randomly assigned to receive MRgFUS (n=27) using the ExAblate 2000 system or UAE (n=22). Women (n=34) who declined randomization were enrolled in a parallel observational cohort to receive MRgFUS (n=16) or UAE (n=18). A comprehensive cohort design was used for outcomes analysis and included 43 patients for MRgFUS and 40 for UAE. The primary outcome measured for additional interventions, including hysterectomy, myomectomy, UAE, or MRgFUS, for symptomatic fibroid tumors within 36 months. The secondary

outcomes compared quality of life, pain, fibroid symptom scores and assessed the effect of treatment of ovarian reserve which was measured using serum anti-Müllerian hormone (AMH) levels. The risk of reintervention was higher with MRgFUS than uterine artery embolization ($p=0.047$). Uterine artery embolization showed a significantly greater absolute decrease in anti-Müllerian hormone levels at 24 months compared to MRgFUS ($p=0.03$). Quality of life and pain scores improved in both arms but to a greater extent in the uterine artery embolization arm ($p=0.006$). Higher pretreatment AMH level and younger age at treatment increased the overall risk of reintervention. Author noted limitations included the small patient population, not all patients completed questionnaires during follow-up visits and the MRgFUS device used throughout the study has now been superseded by newer technology. The authors concluded that there is a lower reintervention rate and greater improvement in symptoms following uterine artery embolization, although some of the effectiveness may come through impairment of ovarian reserve.

A Hayes Technology Assessment (2019a) reviewed the available evidence on MRgFUS for uterine fibroids ($n=6$ studies). The evidence consisted primarily of cohort studies and one RCT with a range of 20–197 patients per study. Comparators were abdominal hysterectomy (1 study), laparoscopic myomectomy (1 study), uterine artery embolization (UAE) (3 studies), and sham (1 study). Outcomes measured included symptom severity, QOL, recovery, fibroid re-intervention, fertility/pregnancy, fibroid volume and adverse events. Follow-up ranged from six weeks to five years. Studies were primarily found to be of poor quality with a single RCT. The RCT performed by Jacoby et al. (2016) was a placebo-controlled pilot study ($n=20$ women) with 24 months of follow-up. According to the Hayes report, results from this trial suggest that treatment with MRgFUS results in statistically significant reductions in fibroid size, but MRgFUS patients also reported statistically significantly higher levels of abdominal or pelvic pain. Limitations of the RCT included a small sample size, lack of power analysis, and substantial loss to follow-up, as well as evidence of a placebo effect. Based on the overall analysis, it was concluded that results consistently suggest that MRgFUS did not perform as well as uterine artery embolization (UAE) in measures of symptom severity, quality of life, and reintervention rates; however, none of the eligible studies adequately evaluated fertility outcomes. The overall quality of the evidence is low due to individual study quality, the lack of well-designed controlled studies and the lack of evaluation of fertility and pregnancy outcomes. Hayes concluded that there is uncertainty regarding the comparative effectiveness of MRgFUS due to inconsistent results across comparative studies suggesting that MRgFUS did not perform as well as alternative minimally invasive treatments and did not improve outcomes in comparison with hysterectomy, with the exception of adverse events. However, the lack of evidence evaluating the effectiveness of MRgFUS in maintaining fertility limits definitive conclusions that can be drawn regarding the comparative benefit.

Barnard et al (2017) published the results of a randomized controlled trial (RCT) and comprehensive cohort analysis which compared periprocedural outcomes of fibroid uterine artery embolization (UAE) and focused ultrasound (MRgFUS) in premenopausal women with symptomatic uterine fibroids. Women were included in the study if they were premenopausal with symptomatic fibroids, at least 25 years old, uteri less than 20 gestational weeks in size and not actively trying for pregnancy. The patients in the RCT ($n=49$) were randomly assigned to receive UAE ($n=22$) or MRgFUS ($n=27$). Whereas patients in the non-randomized PC1 group ($n=34$), were treated with UAE ($n=18$) or MRgFUS ($n=16$). The two treatment groups were analyzed using a comprehensive cohort design (CCD) which combined the RCT group and the PC1 group by treatment type UAE ($n=40$) or MRgFUS ($n=43$). The objective of the study was to summarize treatment parameters, compare recovery trajectory and adverse events in the first 6 weeks following treatment. A total of eight patients were lost to follow-up. Post procedure pain and the increased use of opioids and nonsteroidal anti-inflammatory medications were significantly higher after uterine artery embolization when compared to the focused ultrasound group ($p=0.002$; $p<0.001$; $p<0.001$, respectively). Furthermore, the embolization group had a significantly longer median recovery time ($p<0.001$) and missed more days of work ($p=0.02$). There were no significant differences in the incidence or severity of adverse events between treatments. Author noted limitations included: small patient population, (specifically a low enrollment of black patients), short-term follow-up, the unblinded nature of the study, lack of randomization across groups and the system used for MRgFUS (ExAblate 2000) was older than what is currently used (ExAblate 2100).

Ji et al. (2017) published a meta-analysis of the evidence ($n=16$ studies/1725 women) evaluating the treatment of symptomatic uterine fibroids with HIFU ($n=878$ patients) compared to other approaches (e.g., mifepristone, myomectomy or hysterectomy [MYC/HRM], radiofrequency ablation) ($n=847$ patients). The analysis included RCTs ($n=11$ studies), retrospective control ($n=2$ studies) and an unknown study category ($n=2$ studies).

Response rate was the primary endpoint. All included studies defined complete response as the disappearance of fibroids and patient symptoms, or the reduction of fibroids volume by more than 80%. Partial response was defined as the reduction of fibroids volume from 20 to 79%, and symptom relief. Secondary outcomes included significant clinical complications or adverse events. In the overall analysis, the completely or partial response rate was not found to be significantly higher than other methods. However, the response rate for subgroup analysis by different comparison groups, was significantly higher than mifepristone ($p=0.00$), significantly lower than radiofrequency ablation ($p=0.03$), and comparable to MYC/HRM ($p=0.12$). The overall difference in the rates of complications or adverse events (e.g., pain/discomfort, fever, transfusion) was found to be significant ($p=0.00$) in favor of HIFU compared to traditional surgery or medical treatment. Limitations of this review include the small sample sizes and overall poor quality of studies. Although the results of this meta-analysis suggest that HIFU may be an effective treatment alternative for uterine fibroids, additional larger, well designed, RCTs are need to validate these findings.

A comparative uncontrolled study ($n=192$) by Taran et al. (2009) reported a lower number of complications and adverse events for women who underwent MRgFUS ($n=109$). However, at six months of follow-up, most of the SF-36 subscale scores were significantly better for women in the hysterectomy group ($n=83$).

The results of a number of prospective and retrospective case series ($n=35$ – 359 subjects) suggest that MRgFUS may reduce fibroid volume and improve symptoms over the short term (Gorny, et al., 2011; Funaki, et al., 2009; Morita, et al., 2008; Fennessy, et al., 2007; Rabinovici, et al., 2007). However, limitations of these studies include short follow-up, and for some trials, very small sample sizes.

The Agency for Healthcare Research and Quality (AHRQ) published a comparative effectiveness review on the management of uterine fibroids. The review evaluated six studies which assessed HIFU for fibroid ablation, but only one study used magnetic resonance imaging (MRI) guidance. The authors concluded that although HIFU reduced fibroid and uterine size, the evidence was low due to short term follow-up and poor study design. Furthermore, the evidence related to patient reported outcomes was insufficient (Hartmann, et al., 2017).

Although some of the available data suggest that MRgFUS holds promise, the role of this procedure in the management of patients with fibroids has not been established at this time.

Professional Societies/Organizations

American College of Obstetricians and Gynecologists (ACOG): The ACOG practice bulletin on the alternatives to hysterectomy in the management of leiomyomas stated that “whereas short-term studies show safety and efficacy, long-term studies are needed to discern whether the minimally invasive advantage of MRI-guided focused ultrasound surgery will lead to durable results beyond 24 months” (ACOG, 2008; Reaffirmed 2019).

American College of Radiology (ACR): ACR stated that there is little long-term information on the efficacy of MR-guided high-intensity focused ultrasound (HIFU or MRgFUS) in treating fibroids as the long-term data and viability results are lacking (ACR 2009; Reaffirmed 2017).

Essential Tremor

Essential tremor (ET) is a common movement disorder characterized by postural tremor of the outstretched upper limbs that is absent at rest, not worsened by movement, and not associated with extrapyramidal or cerebellar signs. For most individuals with ET, symptoms can be managed with medication (e.g., propranolol and primidone). Approximately 10% of patients have medically refractory ET that can cause disabling tremor. If medications fail to provide adequate relief, patients with severe, chronic and medically intractable ET become candidates for deep brain stimulation or surgical interventions (e.g., thalamotomy and pallidotomy). The surgical procedures are generally effective, but also carry the risks of open neurosurgery.

The Exablate Neuro has been proposed as technique used to perform a non-invasive thalamotomy by destroying tissue within the Vim nucleus of the thalamus which enables an accurate and controlled thermal effect. Ultrasound energy is delivered across the skull, without an incision or craniotomy. The treatment is done with mild sedatives over several hours and is reported to be generally well tolerated.

U.S. Food and Drug Administration (FDA): In July 2016, the FDA granted a PMA for the ExAblate Model 4000 Type 1.0 System (i.e., ExAblate Neuro) (InSightec—North America, Dallas, TX). The device is indicated for the unilateral thalamotomy treatment of idiopathic essential tremor patients with medication-refractory disease. Patients must be at least 22 years of age. The designated area in the brain responsible for the movement disorder symptoms (i.e., ventralis intermedius) must be identified and accessible for targeted thermal ablation by the ExAblate device. In addition to the RCT upon which PMA approval was based (Elias, et al., 2016), the manufacturer is required to conduct a post-approval study to evaluate safety and effectiveness of the ExAblate Neuro device in patients treated in the pivotal clinical trial through five years post-operatively (FDA, 2016).

On December 16, 2018, the ExAblate Model 4000 received FDA PMA supplemental approval (P150038/S006). The device is indicated for the unilateral thalamotomy treatment of tremor-dominant Parkinson's disease with medication-refractory tremor. Patients must be at least age 30.

Literature Review/Essential Tremor: There is a paucity of studies evaluating the safety and effectiveness of MRgFUS for essential tremor. Mohammed et al. (2018) published the results of a meta-analysis evaluating the outcomes and complications of magnetic resonance-guided focused ultrasound (MRgFUS) in the treatment of essential tremor (ET). Nine studies with 160 patients who had ET were included in the meta-analysis. One randomized controlled trial, six retrospective studies, and two prospective studies were included in the review. The aim of the study was to analyze the outcome of MRgFUS therapy in the treatment of ET. The outcome parameters analyzed were changes in the Clinical Rating Scale for Tremor (CRST) score and improvement in quality of life and disability following treatment using the Quality of Life in Essential Tremor Questionnaire (QUEST) score. The included studies evaluated the presence of a visible and present bilateral postural tremor of the hands and forearms, lasting for more than five years, confirmed diagnosis of ET and treated with MRgFUS. The included cases were refractory to medical therapy. Medication-refractory tremor was defined as a persistent disabling tremor despite at least two trials of a full-dose therapeutic medication, one of which had to include propranolol or primidone. On meta-analysis, the pooled improvement in the CRST Total, CRST Part A, CRST Part C, and QUEST scores were 62.2%, 62.4%, 69.1%, and 46.5%, respectively. The improvement in the score reflects the reduction in the severity and associated disability due to the tremor. The most common complications that occurred during the procedure were headache along with nausea and vomiting occurring in 43.4% and 26.8%, respectively. At three months the most common complication was Ataxia occurring in 25.1% of patients. At 12 months, paresthesias became the most common persisting complaint (15.3%) with ataxia completely resolving in a majority of patients. Limitations of the study include short term follow-up, small patient population, and the included studies were primarily retrospective. Larger trials with randomization are needed to validate the outcomes of this study.

A Hayes Technology Directory report (2019b) evaluated the evidence (n=5 studies) on the efficacy of unilateral MRgFUS thalamotomy for the treatment of essential tremors. The review included one fair-quality randomized controlled trial (RCT), one poor-quality pretest/posttest study, two very-poor-quality retrospective cohort studies and one very-poor-quality retrospective chart review. Study sample sizes ranged from 23–82 patients with follow-ups ranging from three months to five years. Comparators included deep brain stimulation (DBS) in two studies, radiofrequency thalamotomy in one study, and sham treatment in one study. The outcomes measured the effectiveness and safety of treatment using patient reported or objective assessment of tremors, disability, quality of life, cognitive/neuropsychological function and complications. Overall, results suggest statistically significant improvements in QOL, although comparative evidence is inconclusive. Conclusions regarding the safety profile of unilateral MRgFUS thalamotomy across studies are limited because assessments of treatment related AEs were heterogeneous and variable. Hayes concluded that based on very-low-quality body of evidence, results suggest that unilateral MRgFUS thalamotomy may result in a statistically significant improvement in contralateral hand tremor. However, the clinical significance of this improvement has not been established. Additionally, MRgFUS did not result in improvements in axial tremors of the head, trunk, voice, or ipsilateral tremors. Substantial uncertainty arises from the individual study quality, inconsistency in the evidence, and lack of comparative evidence.

Elias et al. (2016) published the results of a randomized controlled trial (RCT) that evaluated the effectiveness of HIFU for the treatment of essential tremor. Patients (n=76) with moderate-to-severe essential tremor that had not responded to at least two trials of medical therapy were randomized in a 3:1 ratio to undergo unilateral focused ultrasound thalamotomy (n=56) or a sham procedure (n=20). The primary outcome was the between-group

difference in the change in hand tremor from baseline to three months, at which time patients in the sham-procedure group were allowed to cross over to active treatment (open-label extension phase). The secondary outcomes were measured in the HIFU thalamotomy group at 12 months and included functional limitations in daily activities, quality of life, and the durability of the reduction in hand tremor. At three months, a statistically significant improvement in hand-tremor scores was found after HIFU thalamotomy versus after the sham procedure ($p < 0.001$). Assessments of disability and quality of life at three months also demonstrated improvement with active treatment compared to the sham procedure ($p < 0.001$). The improvement in the thalamotomy group was maintained at 12 months. Adverse events in the thalamotomy group included gait disturbance in 36% of patients and paresthesia or numbness in 38%, which persisted at 12 months in 9% and 14% of patients, respectively. A total of 21 participants (19 assigned to the sham procedure group who crossed over to thalamotomy and two assigned to thalamotomy in whom the procedure was incomplete) were treated after the three month blinded assessment period. Limitations of the study include small sample size and a lack of comparison to standard treatment (e.g., deep brain stimulation). Additional data from well-designed RCTS are needed to support the use of MRgFUS for essential tremor.

Chang et al. (2018) published the two year results of the open-label extension phase conducted by Elias et al. Follow-ups were conducted at six, 12 and 24 months. Seventy patients were included in the analysis at the one year follow-up, and 67 patients were analyzed at the two year follow-up. Mean hand tremor score at baseline improved by 55% at six months, 53% at 12 months and 56% at two years ($p < 0.001$). Similarly, the disability score at baseline improved by 64% at six months and the improvement was sustained at one year. At two years, mean score was 60% ($p < 0.001$). Paresthesias and gait disturbances were the most common adverse effects at one year with no new complications at two years. Author noted limitations included differences and discrepancies between these findings and the previous report specifically, the number of reported patients was different; 56 subjects in the previous report were compared to the 20 sham-treated patients, but here all 76 patients were analyzed. Additionally the follow-up was two years here versus one year and nine patients dropped out of the study by two years. The authors concluded that tremor suppression after MRgFUS thalamotomy for ET is stably maintained at two years. However, additional follow-up is needed to determine the incidence of recurrence and the efficacy of MRgFUS over the long term.

Insufficient evidence exists in the published peer reviewed medical literature to permit conclusions on the role of this therapy in the treatment of movement disorders.

Miscellaneous

Isolated case series have been published for HIFU/ MRgFUS used to treat indications such as brain, breast and pancreatic cancers, and glaucoma. This evidence is inadequate to make determinations regarding safety and effectiveness.

Centers for Medicare & Medicaid Services (CMS)

- Local Coverage Determination (LCD): Multiple LCDs found. Refer to the LCD table of contents link in the reference section.

Use Outside of the US

Essential Tremor: ExAblate Neuro (InSightec Ltd.) received CE marking approval for the treatment of essential tremor, tremor-dominant Parkinson's disease and neuropathic pain in December 2012.

A 2018 National Institute for Clinical Excellence (NICE) guidance stated that evidence on the safety of unilateral MRI-guided focused ultrasound thalamotomy for treatment-resistant essential tremor raises raised no major safety concerns, but evidence on its efficacy was limited in quantity. NICE concluded that this procedure should not be used unless there are special arrangements for clinical governance, consent, and audit or research. Further research is encouraged and should be in the form of randomized controlled trials. The randomized controlled trials should address patient selection, report on functional improvement and quality of life, and provide long-term follow-up data.

Glaucoma: A 2019 National Institute for Clinical Excellence (NICE) guidance stated that the evidence is inadequate in quality and quantity on the safety and efficacy of high-intensity focused ultrasound for treating

glaucoma. Therefore, this procedure should only be used in the context of research in the form of randomized controlled trials comparing the procedure to standard therapies and should report the safety and long term outcomes (NICE 2019a).

Thyroid Nodules: A 2019 National Institute for Clinical Excellence (NICE) guidance stated that evidence on the safety of high-intensity focused ultrasound for symptomatic benign thyroid nodules raises raised no major safety concerns, but evidence on its efficacy was limited in quantity. NICE concluded that this procedure should not be used unless there are special arrangements for clinical governance, consent, and audit or research. Further research should include details of patient selection, nodule size and position, and whether the nodule is cystic (NICE 2019b).

Prostate Cancer: The following HIFU devices have CE marking in the European Union (Hayes, 2017):

- Sonablate 450/500 (SonaCare Medical LLC) (2015)
- Ablatherm Maxis (EDAP TMS, formerly EDAP Technomed Inc.) (2000)
- Ablatherm Integrated Imaging (EDAP TMS) (2005)
- Focal One (EDAP TMS) (2013)
- Model JC Focused Ultrasound Tumor Therapeutic System (Chongqing Haifu Medical Technology Co. Ltd.) (2005)

The 2018 European Association of Urology (EAU), European Society for Radiotherapy & Oncology (ESTRO), European Society of Urogenital Radiology (ESUR) and International Society of Geriatric Oncology (SIOG) joint guideline on prostate cancer stated that the use of HIFU to treat clinically localized prostate cancer should only be offered in clinical trials. The guideline also stated that there is a lack of data provide any recommendations regarding the use of HIFU when there is a recurrence of prostate cancer following radiation (Mottet, et al., 2019).

A 2012 National Institute for Clinical Excellence (NICE) guidance stated “Current evidence on focal therapy using high-intensity focused ultrasound (HIFU) for localized prostate cancer raises no major safety concerns. However, evidence on efficacy is limited in quantity and there is a concern that prostate cancer is commonly multifocal.” According to the NICE, further research is encouraged and should be in the form of controlled studies with clearly defined patient selection criteria, comparing HIFU to other types of treatment (NICE, 2012).

Uterine Fibroids: The National Institute for Clinical Excellence (NICE) guidance for MRI-guided transcuteaneous focused ultrasound for uterine fibroids stated that the current evidence on the efficacy is adequate, although further treatment may be required and the effect on subsequent pregnancy is uncertain. There are well-recognized complications but the evidence on safety is adequate support the use of the procedure providing that normal arrangements are in place for clinical governance and audit. According to the NICE, further research studies should report long-term outcomes including the need for further treatment (NICE, 2011, Updated 2012).

Coding/Billing Information

- Note:** 1) This list of codes may not be all-inclusive.
 2) Deleted codes and codes which are not effective at the time the service is rendered may not be eligible for reimbursement.

Considered Medically Necessary when used as a local treatment for recurrent prostate cancer following radiation therapy when criteria are met:

CPT®* Codes	Description
55899	Unlisted procedure, male genital system

HCPCS Codes	Description
C9747	Ablation of prostate, transrectal, high intensity focused ultrasound (HIFU), including imaging guidance

Considered Medically Necessary when used for pain palliation in an individual with metastatic bone cancer who has failed or is not a candidate for radiotherapy when criteria are met:

HCPCS Codes	Description
C9734	Focused ultrasound ablation/therapeutic intervention, other than uterine leiomyomata, with magnetic resonance (MR) guidance

Considered Experimental/Investigational/Unproven:

CPT® Codes	Description
76999	Unlisted ultrasound procedure (eg, diagnostic, interventional)
0071T	Focused ultrasound ablation of uterine leiomyomata, including MR guidance; total leiomyomata volume less than 200 cc of tissue
0072T	Focused ultrasound ablation of uterine leiomyomata, including MR guidance; total leiomyomata volume greater or equal to 200 cc of tissue
0398T	Magnetic resonance image guided high intensity focused ultrasound (MRgFUS), stereotactic ablation lesion, intracranial for movement disorder including stereotactic navigation and frame placement when performed
